Play the winner - the design

Stage 1

Stage 2

Experimental treatment A

Let's say **Experimental Treatment B** wins over **A** in Stage 1

Experimental treatment B

Control

Data used in the final (B, as it happened, vs Control) analysis

Play the winner - the model and estimand

Stage 1

Stage 2

Experimental treatment A

$$y_{1A} \sim N(\mu_0 + \mu_A + \eta_1, \sigma)$$

Let's say **Experimental Treatment B** wins over **A** in Stage 1

Experimental treatment B

$$y_{10} \sim N(\mu_0 + \eta_1, \sigma)$$

Control

$$y_{2B} \sim N(\mu_0 + \mu_B + \eta_2, \sigma)$$

Data used in the final (B, as it happened, vs Control) analysis

The frequentist analysis: it is difficult to avoid bias on the estimate of μ_{OPT} (index OPT defined as the treatment that appeared to be superior)

Suppose $\mu_B = \mu_A = 0$. The naive estimator $\hat{\mu}_B = m_B - m_0$ is biased because, by design $m_B > m_A$ so it is plausible that is also $m_B > 0$.

$m_B - m_A > 0$ is biased for $\mu_B - \mu_A = 0$.

$m_B - m_A = 0$ is biased for $\mu_B - \mu_A > 0$.

Posterior mean of μ_{OPT} (say, OPT = B)

If $\mu_B > \mu_A$, $\text{Epost}(\mu_{\text{OPT}}) = m_B$

If $\mu_B < \mu_A$, $\text{Epost}(\mu_{\text{OPT}}) = m_A$

So:

$\text{Epost}(\mu_{\text{OPT}}) = \text{post}(\mu_B > \mu_A) m_B + \text{post}(\mu_B < \mu_A) m_A$

Every effect size estimator is biased in the frequentist sense

An estimator $\hat{\theta}$ for θ is said to be unbiased if for every hypothetical true θ , the expected bias is zero

$$\forall \theta: E(\hat{\theta} - \theta | \theta) = 0$$

Suppose $\theta = 0$. Since $\hat{\theta} \geq 0$ by design, the only unbiased estimator is $\hat{\theta} = 0$. Which is biased for every other value of θ !

Beyond play-the winner

Suppose you want to develop a new biomarker (or therapeutic target)

You find umpteen candidates that have been studied and reported in the literature

You cherry-pick the one that reportedly worked best!

Q:

What effect size do you assume for you sample size calculations etc?
